Syntax

- Return a DataFrame containing binary columns:

```
dummy_df = pd.get_dummies(cars["cylinders"])
```

- Concatenate DataFrames:

```
cars = pd.concat([cars, dummy_df], axis=1)
```

- Return a Series containing the index of the maximum value:

```
predicted_origins=testing_probs.idxmax(axis=1)
```

Concepts

- In the instance where 2 values are just 2 different labels, it is safer to turn the discrete values into categorical variables.
- Dummy variables are for columns that represent categorical values.
- A problem is a multiclass classification problem when there are three or more categories or classes. There are existing multiclassification techniques that can be categorized into the following:
 - **Transformation to Binary:** Reduce the problem to multiple binary classification problems.
 - **Extension from Binary:** Extend existing binary classifiers to solve multi-class classification problems.
 - **Hierarchical classification:** Divide the output into a tree where each parent node is divided into multiple child nodes and the process is continued until each child node represents only one class.
- The one-versus-all method, which is a transformation to binary technique, is a technique where we choose a single category as the Positive case and group the rest of the categories as the False case.
