

# Clustering basics: Takeaways

by Dataquest Labs, Inc. - All rights reserved © 2021

## Syntax

- Compute the Euclidean distance in Python:

```
from sklearn.metrics.pairwise import euclidean_distances
euclidean_distances(votes.iloc[0,3:], votes.iloc[1,3:])
```

- Initialize the KMeans class from scikit-learn:

```
from sklearn.cluster import KMeans
kmeans_model = KMeans(n_clusters=2, random_state=1)
```

- Calculate the distance between observations and the clusters:

```
senator_distances = kmeans_model.fit_transform(votes.iloc[:, 3:])
```

- Compute a frequency table of two or more factors:

```
labels = kmeans_model.labels_
print(pd.crosstab(labels, votes["party"]))
```

## Concepts

- Two major types of machine learning are supervised and unsupervised learning. In supervised learning, you train an algorithm to predict an unknown variable from known variables. In unsupervised learning, you're finding patterns in data opposed to making predictions.
- Unsupervised learning is commonly used with large datasets when it isn't certain how to start with supervised machine learning. It's beneficial to try unsupervised learning to explore a dataset before using supervised machine learning models.
- Clustering is a main unsupervised learning technique. Clustering algorithms group similar rows together and is a key way to explore unknown data.
- We can use the Euclidean distance formula to find the distance between two rows to group similar rows. The formula for Euclidean distance is:

$$d =$$

$$\sqrt{(q_1 - p_1)^2 + (q_2 - p_2)^2 + \dots + (q_n - p_n)^2}$$

where  $q_n$  and  $p_n$  are observations from each row.

- The k-means clustering algorithm uses Euclidean distance to form clusters of similar items.
